

Introduction and Motivation

Constructing an optimal batting order is a fundamental and recurring challenge in baseball, faced by managers at every level of the sport. Traditionally, lineup construction has been guided by a mixture of statistical reasoning and longstanding heuristics (for example, placing high on-base percentage hitters at the top of the order and power hitters in the middle). However, a lineup determines not only the sequence in which players bat, but also how often high-impact hitters come to the plate and how effectively offensive opportunities are converted into runs. These conventions, while intuitive, often fail to fully leverage the depth and granularity of modern player performance data. With the advent of Major League Baseball's Statcast system, teams now have access to highly detailed, pitch-by-pitch data capturing nuanced aspects of player performance, such as exit velocity, launch angle, and expected outcomes of batted balls. This creates an opportunity to explore whether machine learning methods can provide a more systematic, data-driven approach to lineup construction, potentially uncovering patterns not immediately apparent through conventional analysis.

In this project, we develop a two-model machine learning framework to study and predict batting order decisions. The first model operates at the player level, using offensive performance metrics to predict a probability distribution over the nine possible lineup positions. The second model builds on this representation by considering groups of nine players simultaneously, learning to predict a complete lineup configuration. By leveraging learned player embeddings and modeling interactions across players within a lineup, this approach aims to better approximate the joint decision-making process underlying real-world lineup construction. This framework extends prior work in operations research that models baseball as a probabilistic

system, where lineup construction can be analyzed as an optimization problem, and player sequencing influences run production.¹ While these approaches have provided valuable insights, they typically rely on fixed probabilistic assumptions.² In contrast, our method uses data-driven representations learned directly from high-dimensional Statcast features, allowing for greater flexibility in capturing complex, nonlinear relationships between player performance and lineup placement.

Our analysis is driven by two primary research questions. First, how accurately can we predict a player's lineup position based solely on their performance metrics up to a given point in the season? Second, which player attributes are most influential in determining lineup placement? More broadly, we seek to understand the extent to which lineup decisions in professional baseball can be explained and potentially replicated through statistical learning methods. The motivation for this work stems from both a personal passion for baseball and the richness of its data. From a machine learning perspective, the problem presents an interesting combination of classification and structured prediction tasks, while the sport itself still relies heavily on human judgment in strategic decisions. By applying modern learning techniques to lineup construction, we aim to bridge the gap between data availability and decision-making, providing insight into how quantitative methods can complement or challenge traditional approaches to the game.

Data Description

The data for this project was sourced using the Python package `pybaseball`, which provides programmatic access to several major baseball databases, including Baseball Savant, Baseball Reference, and FanGraphs.³ Specifically, we used the `statcast` function to retrieve pitch-by-pitch data for the entire 2025 Major League Baseball season. The raw Statcast dataset contains 118 variables per pitch, including pitch characteristics (location, velocity, spin rate), game context, player identifiers, and batted ball outcomes. To ensure consistency and representativeness of player performance, we restricted the dataset to players with at least 100 plate appearances during the season. We also standardized player identifiers using the `playerid_reverse_lookup` function, allowing us to consistently match players across datasets.⁴ In addition to Statcast data, we incorporated a game log dataset containing the batting order for each team in each game, including game date and home/away team designations. These two sources were merged using shared identifiers such as game date and team.

The unit of analysis in our final dataset is a player-game instance, where each row represents a single player's performance entering a specific game, along with their observed lineup position in that game. To construct meaningful input variables, we transformed pitch-level data into cumulative player statistics calculated up to each game date. These features were designed to capture multiple dimensions of offensive performance, including traditional rate statistics such as batting average (AVG), slugging percentage (SLG), and on-base percentage (OBP), and more advanced metrics like expected weighted on-base average (xwOBA). These

⁴ Tools such as the Chadwick Register (which can also be accessed through `pybaseball`) offer easy ways to choose between ID methods. The most up-to-date version is MLBID, but we choose to use Retrosheet which is more commonly used for historical data since that was the key type used by our game log of every lineup.

variables were selected to provide a balanced representation of hitting ability, plate discipline, and quality of contact.

To prevent data leakage and better reflect real-world decision-making, all features were computed as cumulative statistics up to, but not including, the current game. This was implemented using cumulative sums with a one-step shift. Additional data cleaning steps included removing rows with missing lineup positions (e.g., pinch hitters), ensuring there was always only one observation per player per game, and filtering out each player's first 10 games of the season to allow performance metrics to stabilize. The final dataset consists of 36,665 player-game observations across the 2,430 games of the 2025 MLB season. Each observation includes 11 engineered performance features, contextual variables such as game date, team, and player ID, and the target variable representing lineup position (1–9).

Results

As seen in the model evaluation output, the player-level model demonstrates that lineup position can be predicted with meaningful accuracy using offensive performance metrics (Fig. 2). It achieves an exact accuracy of 51.28% and a mean absolute error of 1.01. We also evaluated the model's ability to have the true lineup position within its top 3 predictions, resulting in a proportion of 83.78% of players. Additionally, training loss decreased steadily to just above 1.0 over 100 epochs, while the validation loss achieved a minimum of approximately 1.3 and showed limited improvement beyond that point (Fig. 3). In the context of a nine-class

classification problem using cross-entropy loss, this gap suggests that the model successfully captures structure in the training data but begins to overfit, with diminishing returns in generalization performance after early epochs. These results suggest that while exact classification across nine possible positions is inherently difficult, the model captures strong signals about where a player generally belongs in the batting order. The second, team-based model reflects the increased difficulty of predicting all nine positions simultaneously. It achieves an exact match rate of 12.38%, which is low but expected given the combinatorial complexity of full lineup prediction ($9!=362880$). More informative metrics help us show this relatively strong performance, with an average displacement of 0.76 positions per player and a pairwise accuracy of 87.66% (Percentage of pairs of 2 players in which the model correctly guessed which player batted before the other). In other words, even when exact positions differ, the model typically places players in approximately the correct part of the lineup. Position-specific accuracy further supports this, with top-of-the-order spots predicted most accurately and middle-to-lower positions showing more variability.

Interpreting these results reveals that both models have learned patterns consistent with established baseball strategy. Feature importance analysis from the player model shows that HardHit%, xwOBA, and HR are the most influential predictors, suggesting that quality of contact and power are key drivers of lineup placement. This aligns with the tendency for high-impact hitters to appear in the middle of the order. At the same time, relatively strong accuracy at the top of the lineup indicates that the team model also captures the importance of on-base and contact-oriented metrics for leadoff and early-order roles, whereas lower lineup positional roles are less clearly defined and more dependent on contextual factors not included in the data. Despite this, several of our earlier approaches did not perform as well by these metrics

and subsequently informed the final model design. Notably, we had to tune the thresholds by which we filtered out players that did not appear in enough games. However, this had to be balanced with the need for as much data as possible in order to maximize sample count for the team-based lineup prediction model (which would only use a sample if all 9 position slots were filled with a valid player feature entry). On the modeling side, earlier versions that treated lineup positions as independent classes without accounting for their ordinal relationships produced less stable training behavior and larger positional errors, even with a much larger epoch count (Fig. 4). Through repeated testing and tuning of model parameters, these issues were addressed and improved overall predictive performance.
